#### Abstract

The bright blue straggler NSV 4276 in the old open cluster M67 was found to be an eclipsing binary with an orbital period of 1.0678 . Five primary and one secondary eclipses were detected. The amplitude of variability is 0.12 both in B and V . The primary eclipse depth is 0 m. 0 . The effect of ellipsoidality of the bright companion is seen. It is supposed that this star overflows its Roche lobe on the way to red giants, and that the system is a semidetached binary.

KEY WORDS Eclipsing binaries, periods, orbital variability

## 1. INTRODUCTION

The microvariability of NSV 4276, a blue straggler in the old open cluster M67, was first reported by Danziger and Dickens (1967); the dispersion of measurements was 0 m. 007 during 81 minute monitoring. Earlier a photoelectric search for light variability in a dozen so-called "horizontal-branch stars" in M67 had been carried out by Sears (1965), NSV 4276 being one of them. No variations more than 0.1 were found, but the observations were not sufficient to exclude all possible periods. Later, Chiu (1970) reported his discovery of four variables in a sample of nine horizintal branch stars with amplitudes of $0.02-0 \% .03$, and periods of the order of several hours. No specific star names were given.

Two of us (Mironov and Pastukhova, 1980) observed three of these horizontalbranch stars in December 1979 and confirmed small-amplitude variability of NSV 4276. But in a new set of observations in February 1981 they discovered a small-amplitude eclipse-like event in NSV 4276. During the following nine years we searched for light minima to determine the possible orbital period. We now have five primary and one secondary minima, which may make it possible.

NSV 4276 is also known as F131 (Fagerholm, 1906), vM160 (van Maanen, 1942), RGO417 (Murray et al., 1965), and S1082 (Sanders, 1986). One can find the identification charts of the star in the two last cited papers, and in the paper by Racine (1971). Its accurate co-ordinats concerning to Epoch of 1950.0 are the following: $8^{\mathrm{h}} 48^{\mathrm{m}} 36^{\mathrm{s}} .6214,+12^{\circ} 04^{\prime} 43^{\prime \prime} .239$, Equinox 1950.0 (Girard et al., 1989). $V=11^{\mathrm{m}} .25, B-V=0^{\mathrm{m}} 40, U-B=0^{\mathrm{m}} 05$, Sp. F0 - F4IV (Eggen, Sandage, 1964; Eggen, 1981). The star is a proper-motion member of the cluster. The radial
velocity $V_{\mathrm{r}}=+14 \pm 3.2 \mathrm{~km} \cdot \mathrm{~s}^{-1}$ measured by Pesch (1967) made cluster membership doubtful. The calibration in the colours of Stroemgren uvby-photometry was another argument against membership (Eggen, 1981). But numerous modern CORAVEL observations by Mathieu et al. (1986) give a mean value of $V_{\mathrm{r}}=33.5 \pm 2.0 \mathrm{~km} \cdot \mathrm{~s}^{-1}$, supporting membership. Girard et al. (1989) give 99 per cent membership probability based both on proper motion and radial velocity. Moreover, the usually high scattering of $V_{\mathrm{r}}$ in the range of 30.3 and $37.7 \mathrm{~km} \cdot \mathrm{~s}^{-1}$ suggests that the star is a binary, which may be a cause of difficulties in photometric calibration. The orbital solution nevertheless is not yet found, and no evidence of the secondary companion is found in the spectrum.

## 2. OBSERVATIONS

The observations were carried out with five different pulse-counting photoelectric photometers in the B and V photometric bands. Two $60-\mathrm{cm}$ Zeiss reflectors of the Sternberg Institute Crimean observatory and the $48-\mathrm{cm}$ reflector of the Tian-Shan High-Altitude observatory were used. The comparison star BD $+12^{\circ} 1918$ and check star BD $+12^{\circ} 1920$ were chosen to measure the variable. The magnitudes of these and two other stars in the field of M67 in the WBVR system are given in Table 1. W is a revised ultraviolet photometric band described by Straižys (1967) $\left(\lambda_{0}=3500 \AA, F W H M=500 \AA\right)$. The observations are given in Table 3.

The diversity of devices used in our study and the large difference in colours between the variable and comparison stars prevents us from reducing the observations in a common photometric system accurately. So the light curve level varies by more than 0.05 B and 0.04 V . A clear systematic difference is seen between Crimean and Tian-Shan observations. The appearance of a neighbouring faint cluster star in the photometer diaphragms may be another cause of these variations. But the question whether the components of the system have intrinsic variability remains open. The Tian-Shan observations were made in the better high-altitude sky conditions, so they have higher accuracy than the Crimean ones.

The observations show the depths of primary eclipses to be of 0.07 and the duration of the partial eclipse of approximately 3.6 . The exterior contacts of the eclipse are well seen in the light curve, so the star can be referred to classical Algol-type systems.

Table 1

## 3. EPHEMERIS AND LIGHT CURVE

The period search was made with an EC-1045 computer using the well-known Lafler-Kinman method. The period of 0.5338989 was the best found in the interval of periods tested between 0.4 and 20 days. Analysis of the light curve shows that this value is a half of the real orbital period. The light curve shown in Figure 1 is computed with the next light elements:

$$
\begin{array}{r}
\text { Min I hel }=2444643.253+1.0677978 \cdot \mathrm{E} . \\
\pm 5 \quad \pm 50
\end{array}
$$

The light curve with the given period and two minima is preferable because the two alternate minima have non-equal depth and different shape. The depth of the secondary minimum is twice less than the primary one, and its first contact displays badly.

The orbital period found on the basis of photoelectric photometry nevertheless disagrees with 26 radial velocities given by Mathieu et al. (1986). Any regular pattern or wave is not seen in the radial velocity curve, so we do not reproduce it here. We tried to search the radial velocities for periodicity with the same Lafler-Kinman method but without any satisfactory result. On the contrary, some periods fitting the radial velocity data disagree with photometry. This is a strange result in that the spectra of this bright star obtained by Mathieu et al. have a considerable signal-to-noise ratio, and that the velocities are based on highquality correlation functions. The precision of individual values ranges from 0.3 to $0.8 \mathrm{~km} \cdot \mathrm{~s}^{-1}$, so both photometric and radial velocity data should be verified.

Six moments of minima are given in Table 2.
The total range of the light variations in NSV 4276 are found to be $11.56-11^{\mathrm{m}} .68$ in B , and $11^{\mathrm{m}} .16-11^{\mathrm{m}} .28$ in V . V magnitude in the secondary minimum is 11.24 .

The duration of the primary minimum is 0 p .14 . It is clear that a small and faint companion passes in front of large and bright subgiant at the primary eclipse. The difference in the depths of primary and secondary eclipse suggests that the surface temperatures are slightly different. However, the flat bottom is not seen, which rejects both annular and total eclipses, but supports the partial eclipse hypothesis.

The out-of-eclipse light variations by 0.03 V correlating with the phase of the

[^1]

Figure 1 B and V light curves of NSV 4276. Tian-Shan observations are shown with black points, Crimean ones with open circles. The first discovered eclipse is seen on the lower level in both bands.
orbital period are clearly seen in the Figure 1. This may be an effect of the ellipsoidal shape of the bright F4 subgiant. Our observations do not cover all the phases of the orbital period; there is a gap in the light curve in the phases from 0 P. 53 to 0.74. But one can see that the star brightness in the secondary maximum at the phase of 0.75 is systematically higher than in the primary one at the phase of 0.25 by $0.01-0 \mathrm{~m} .02 \mathrm{~V}$, and that the out-of-eclipse variations are non-symmetric relative to zero phase. The phenomenon, if it really exists, may be a result of the accretion from the bright star and of the hot spot on the surface of the faint star.

## 4. ON THE EVOLUTIONARY PHASE OF NSV 4276

Kholopov (1965) supposed in his photometric and proper motion study of bright stars in M67 that some of them form a horizontal branch resembling that of a globular cluster or Galactic halo stars. These stars distributed over the CMD region between 10.0 and 11 m .6 V blueward of $\mathrm{B}-\mathrm{V}=1 \mathrm{~m} .0$ have absolute magnitudes typical to globular cluster HB stars (see Figure 2). The three reddest horizontal branch stars in M67 were found to be spectroscopic binaries by Mathieu et al. (1990). These stars are plotted in Figure 2 with open squares. The CMD in Figure 2 is built up using data by Eggen and Sandage (1964) and Racine (1971). NSV 4276 and other eclipsing binary in M67 AH Cnc are plotted with crosses.

Remember, AH Cnc (S 1282) is a contact W UMa type binary with an orbital period of 0 d 3604364 (Whelan et al., 1979).

The discovery of spectroscopic binaries and NSV 4276, a new eclipsing binary in the horizontal branch, makes the interpretation of bright stars in M67 as a horizontal branch typical to that of globular clusters questionable. Only metalpoor globular clusters are known to have horizontal branches distributed from blue to red. But M67 with normal metal abundance may be suspected to have a very red one. It seems that a clump of six red stars at $\langle\mathrm{V}\rangle=10.55$ and $\langle\mathrm{B}-\mathrm{V}\rangle=1$. 11 may be a real horizontal branch in M67.

Figure 2 The location of NSV 4276 and other binaries in the colour-magnitude diagram of M67.

Another interpretation of bright stars in M67 as stragglers was given by Eggen (1981). These are main sequence stars delayed in evolution of CMD, supposed to be totally mixed stars after helium flash or binaries overflowing their Roche lobes. In the globular clusters both the binaries and the single pulsating SX Phe type stars are located above the main sequence turn-off point.

It is now clear that the unusual location of NSV 4276 out of the principal CMD sequences is caused by the F4 subgiant overflowing its Roche lobe on the way to the red giant phase. So the system may be expected to be a semidetached binary. The secondary component may be an ordinary main sequence star.
